ABSTRACT

Background. Chronic fatigue syndrome (CFS) and major depressive disorder (MDD) share many symptoms and aetiological factors but may have different neurobiological underpinnings. We wished to determine the profile of the biological variables disturbed in CFS and MDD, and identify any critical factors that differentiate the disorders.

Methods. Thirty patients with CFS, 20 with MDD and 15 healthy controls – matched group-wise for age and sex – were recruited. Subjects were given a detailed battery of motor and cognitive tests, including measures of psychomotor speed, memory and maximal voluntary muscle contraction in both the morning and evening that were balanced to avoid order effects.

Results. CFS patients generally performed worse on cognitive tests than healthy controls, but better than patients with MDD. Both patient groups had markedly impaired motor function compared with healthy controls. MDD subjects showed a significantly greater diurnal improvement in maximal voluntary contraction than healthy controls.

Conclusions. Patients with CFS and MDD show similarly substantial motor impairment, but cognitive deficits are generally more marked in MDD. Diurnal changes in some functions in MDD may differentiate the disorder from CFS.

INTRODUCTION

The nature of chronic fatigue syndrome (CFS) or 'myalgic encephalomyelitis' (ME) remains controversial. Some clinicians and most patients stress that these conditions are primarily post-infectious and that any emotional disturbance is secondary (Behan & Bakheit, 1991). However, 50–70% of CFS sufferers satisfy criteria for psychiatric disorders, particularly depression, which cannot simply be attributed to the effects of prolonged disability (David, 1991; Kendal, 1991). It follows that CFS may share essential aetiological features with mood disorder. Indeed, it may best be thought of as a syndrome

characterized by both fatigue and psychiatric morbidity, triggered by physical and psychosocial stressors, and maintained by biological and psychological factors (Lawrie *et al.* 1997a). Depressive disorder could be described similarly (Kendal, 1991). It is, therefore, important to measure the quantitative similarities and differences between the two disorders.

The present study extends the parallel understanding of CFS and major depressive disorder (MDD) by a detailed investigation of neurobiological indices. There are preliminary studies of motor and cognitive function in CFS and MDD (which form the basis for hypotheses we examined here) but none is definitive and few bring together more than a single domain of investigation. For example, patients with CFS report an increased perception of muscular effort despite submaximal performance on exercise

testing (Stokes *et al.* 1988; Riley *et al.* 1990), but the same may be true in depression, where impairment of motor function extends even to maximal voluntary hand grip (Cohen *et al.* 1982; Moffoot *et al.* 1994). Subjective reports of cognitive impairment in CFS are supported by objective evidence for slowed reaction time and poor memory or attention (Millon *et al.* 1989; Altay *et al.* 1990; Riccio *et al.* 1992; Grafman *et al.* 1993; MacDonald *et al.* 1993; Ray *et al.* 1993; Sandman *et al.* 1993; Schmaling *et al.* 1994; Cope *et al.* 1995; DeLuca *et al.* 1995; Joyce *et al.* 1996; Marcel *et al.* 1996; Marshall *et al.* 1997; Vollmer-Conna *et al.* 1997; Wearden & Appleby, 1997; Johnson *et al.* 1998). A comparison with depression suggests a similar pattern of impairments (e.g. Austin *et al.* 1992). However, both motor and cognitive impairments tend to be maximal in the morning and improve over the day in depression (Moffoot *et al.* 1994; Porterfield *et al.* 1997). By contrast, CFS patients generally report that symptoms worsen in the evening, although there is little objective data on this point.

We have examined a group of CFS patients with measures of isometric strength, subjective effort, mood and an appropriate series of neuropsychological tests, in the morning and evening, and compared them with groups of both depressed and healthy controls. We also measured endocrine function and cerebral perfusion, but provide accounts of these investigations elsewhere (MacHale *et al.* 1998, 2000). We specifically tested the hypothesis that the cognitive and motor impairments in depression and CFS would be expressed similarly as reductions in performance as compared to healthy controls, but with diurnal improvement in depression and evening worsening in CFS.

METHOD

Approval for the project was obtained from the appropriate Ethics Committee.

Subjects

Thirty patients satisfying operationalized criteria for CFS (Fukuda *et al.* 1994) were recruited from the local ME association self-help group ($N = 13$) and from the regional infectious diseases unit ($N = 17$). Where possible, patients were selected to be over 30 years of age so that

clear evidence of the level of pre-morbid function was obtainable. Sixteen subjects were medication-free at the time of assessment, with the remaining 14 being prescribed either antidepressants (10), hypnotics/anxiolytics (4) and/or endocrine replacement (2 on thyroxine, 1 on the oral contraceptive pill). Patients were excluded if there had been any change in their medication in the previous 3 weeks.

Twenty patients with major depression by DSM-III-R criteria (APA, 1987), matched group-wise for age and sex, were recruited from the wards and out-patient services of the Royal Edinburgh Hospital. They were recruited for this study and a within subjects study of diurnal variation in MDD (12 had diurnal variation worst in the morning, eight were worst in the evening) and have not been previously reported. Five MDD patients were medication-free at the time of assessment, with the remaining 15 being prescribed antidepressants (14), hypnotics/anxiolytics (3), thyroxine (2) and/or lithium (1) in doses which had been stable for at least 3 weeks. A healthy control group of 15 subjects was also recruited, matched for age and sex, from hospital staff and friends of the CFS/ME patients.

All subjects received a standardized psychiatric interview, the Schedule for Affective Disorders and Schizophrenia (SADS) (Endicott & Spitzer, 1978) to establish any psychiatric diagnosis. Potential CFS/ME subjects with current co-morbid psychiatric disorders, such as depression, were excluded, but those with a previous history of co-morbid depression were not (Fukuda *et al.* 1994). All subjects also underwent a comprehensive physical examination, and blood screening as thought necessary, to exclude any physical illness that could be responsible for the fatigue or depression. All pre-menopausal female subjects were required to have a negative pregnancy test before inclusion. The severity of depression symptoms were rated using the 17-item Hamilton Depression Rating Scale (HDRS) (Hamilton, 1960). Pre-morbid IQ was assessed with the revised National Adult Reading Test (NART) (Nelson & Willison, 1991).

The Befindlichkeitskala scale (BFS) (Von Zerssen *et al.* 1974) was used to measure levels of depression and fatigue in both the morning and evening. This is a self-rating mood scale, with

Table 1. Clinical characteristics of CFS, MDD and healthy control subjects (CON) (mean (s.d.))

	CFS	MDD	CON
Sex (male/female)	11/19	8/12	4/11
Age (years)	44.2 (10.3)	44.0 (12.1)	41.1 (12.8)

Emotional role limitations	80.0 (34.6)	—	—
Social functioning	36.2 (24.4)	—	—

impressive validity and reliability, in which subjects choose from 28 positive/negative word pairs to describe their state of mind (scoring 2 or 0 respectively, or 1 if undecided, giving a total score range of 0–56 and a range of 0–16 for the depression and fatigue items).

In CFS subjects, the severity of fatigue was scored on the Chalder scale (Chalder *et al.* 1993) while functional impairment was measured with the SF36 (Ware & Sherbourne, 1992). The SF36 is a validated self-report questionnaire, scaled scores giving levels of current functioning that vary from 0 to 100% of normal (other than health transition where scores range from 0–5 with lower numbers reflecting greater improvement over the past year). Demographic data and clinical scores are summarized in Tables 1 and 2.

Cognitive and motor function assessment

A comprehensive battery of neuropsychological tests was administered. The CFS and healthy control groups completed the Block Design subtest of the Wechsler Adult Intelligence Scale-Revised (WAIS-R) (Wechsler, 1981), Verbal Fluency (Benton & Hamsher, 1978), Trails A and B (Reitan, 1958), Paired Associates Learning (PAL) (Wechsler, 1981), the Boston Naming Test (Kaplan *et al.* 1983), the 2- and 4-second versions of the Paced Auditory Serial Addition Test (PASAT) (Brittain *et al.* 1981), and the California Verbal Learning Test (CVLT) (Delis *et al.* 1987).

The CFS and healthy control groups completed a number of tests in both the morning and evening on matched, parallel versions of: digit span forwards and backwards (Randt & Brown, 1983); reaction time measures from the Cambridge Neuropsychological Test Automated Battery (CANTAB) (Sahakian & Owen, 1992); and a sustained hand grip test, which required subjects to maintain a hand grip at 10 kg pressure on a dynamometer, for as long as possible, up to a maximum of 3 min. Immediately after the latter, subjects were asked to complete the Borg effort scale (Borg, 1982).

The remaining cognitive and motor tasks were completed by all subjects in both the morning and evening. The Digit Symbol Substitution Test (DSST) (Wechsler, 1981) was followed by the Auditory Verbal Learning Test, including the delayed recall and recognition sections (AVLT) (Rey, 1964; Lezak, 1983; Crawford *et al.* 1989). The AVLT is a test of immediate, short- and long-term memory. A 15-item list (A) is read aloud to participants who are asked to recall the items immediately and after four consecutive repetitions. A second word list (B) is then presented, which subjects are asked to repeat, before recalling list A again. This first part of the AVLT is usually completed in 15 min. Delayed recall and recognition of list A are then tested after 30 min. Finally, subjects were asked to squeeze a handgrip dynamometer as hard as possible on three occasions in both

hands (averaged to assess maximum voluntary contraction in each hand).

All the diurnal tests were conducted twice in a balanced design, to avoid order effects. Subjects were randomly allocated to being tested first at 8 a.m. and then 8 p.m. of the same day or 8 p.m. followed by 8 a.m. the next morning. Parallel versions of all the repeated tests were used in the second testing session. The order of particular tests was however the same in both sessions.

Statistical analysis

Cognitive and motor tests given to only CFS and control subjects were compared by one-way analysis of variance (ANOVA). The clinical ratings (BFS), cognitive and motor tests completed by subjects in both morning and evening were compared by repeated measures ANOVA with an interaction term for the hypothesized group by time effects. Significant group, time or interaction effects were then examined with planned ANOVA and *post hoc* Scheffé tests to identify the nature of the effects, controlling for multiple comparisons. The analyses were repeated comparing CFS subjects on and off medication.

RESULTS

Subjects

As shown in Table 1, the subject groups were well matched for age and pre-morbid IQ, but male healthy controls were under-represented. The CFS subjects had become ill at an older age than the MDD subjects, but their current (and

only) episode had been longer. As expected, the levels of depressive symptomatology were higher in MDD subjects than CFS subjects, who in turn had higher levels than the healthy controls. The CFS subjects reported high levels of fatigue and were substantially incapacitated as measured by several ratings on the SF36 – particularly in levels of vitality, physical and social functioning and general health. The mean score of 2.9 on health transition indicates that most CFS subjects had not noted much change in their condition over the previous year.

CFS and MDD subjects scored equally high on the BFS fatigue score, but levels of depression were much higher in MDD than CFS patients (see Table 2). Both CFS and healthy subjects tended to report greater levels of symptoms in the evening than in the morning, with the opposite being true in the MDD subjects, but none of the diurnal changes in symptoms was statistically significant.

Cognition

Table 3 shows the results from the neuropsychological tests that were given to CFS and healthy controls on only one occasion. The differences were small. The only statistically significant effect is the fewer total number of words produced on the verbal fluency test. However, the CFS subjects consistently do slightly worse than the healthy controls. (They also show a tendency to do relatively worse, as measured by effect sizes, on 'harder' than 'easier' tests – i.e. scoring lower on Trails B than A, lower on PAL hard than easy pairs, and

lower on PASAT 2 as compared to 4 s – but these differences were not statistically significant on testing with paired *t* tests). This generally poorer performance is also evident in the results from those tests that were given to CFS and healthy control groups in both the morning and evening (see Table 4). CFS subjects had statistically significantly slower reaction times, attributable to movement rather than reaction latency, at both testing times. The results of the digit span backwards test show the predicted differential diurnal pattern of worsening in CFS with improvement in healthy control

groups – although the scores themselves do not generally show a statistically significant deficit in CFS and none of the other tests in this section show diurnal worsening in CFS.

Table 5 shows the results of the tests specifically employed to test our diurnal variation hypothesis – which was not confirmed. Most test results improved, although not to a statistically significant extent, from morning to evening in all three groups. Patients with MDD tended to do worst on all tests at both time points. The only statistically significant group by time interaction is on the digit symbol

substitution test, but *post hoc* testing did not reveal any statistically significant between group diurnal changes.

Motor tests

The results from the sustained hand grip tests are shown in Table 4. CFS patients were able to sustain a 10 kg contraction for less time than the controls in both the morning and evening, and reported greater subjective effort, but these differences were only statistically significant in the evening and the group by time interactions were non-significant.

The mean of three maximal contractions in the right and left hands of all three subject groups are shown in Table 6. The CFS patients' mean scores are very similar to those of the MDD patients, being approximately 25–30 % lower than in healthy controls in both hands at both time points in both groups. Motor performance tended to improve from morning to evening in CFS, as in MDD, but worsen in healthy controls; although the group by time interaction effect is only significant for a greater improvement in MDD than the healthy control group ($P < 0.05$) for the right (dominant) hand.

Controlling for medication status in CFS

All the above neurobiological variables ($N = 42$) were compared between CFS subjects on ($N = 16$) and off ($N = 14$) medication. Although two statistically significant differences ($P < 0.05$) could have occurred by chance alone, no such differences were found. Concomitant medication is therefore unlikely to explain the between group differences described above.

DISCUSSION

Main findings

We report the results from a detailed study of motor and cognitive function in CFS as compared with both depressed and healthy control groups. Patients with CFS and MDD reported similar levels of fatigue and showed similarly large decrements on maximal voluntary contractions. The MDD group had a significantly greater burden of depressive symptoms and more obviously impaired cognitive performance. Patients with CFS do have neuropsychological deficits, but these are subtle and most apparent when information processing demands are highest or after fatiguing exercise (Blackwood *et al.*

1998). We found only limited evidence of differential diurnal effects on cognitive and motor function in CFS and MDD.

Limitations

We recruited some of the CFS subjects from a local self-help group, which may have introduced bias, for example to severity and chronicity. However, there is an approximate 50 % overlap in the local membership and hospital out-patient attenders and any bias would probably have reduced differences between CFS and MDD subjects. Our recruitment strategy means that our results apply to those with CFS as well as to those patients who regard themselves as suffering from 'ME'. It would have been informative to have a group of CFS subjects with depression, but practical considerations dictated our approach. Including medicated CFS subjects, who were usually taking antidepressants for previous depression or current symptomatic relief (of a possible subclinical depression), means that our results are potentially confounded by medication effects (although we did not find any), but also makes them applicable to the majority of CFS patients with co-morbid psychiatric symptoms. Most of our depressed subjects were medicated, as they had presented for treatment, and it is possible that sedative or anticholinergic effects worsened test performance – although the benefits of treating depression probably outweigh any adverse effects in MDD patients (Calev *et al.* 1986).

We are limited in the comparisons that can be made of cognitive function across the three subject groups as the MDD patients only completed some of the tests. However, the results of the AVLT and DSST demonstrated pronounced psychomotor and memory deficits in MDD, which were greater than those in CFS. Although we found some of the predicted differential effects of diurnal variation in CFS and MDD as compared to controls, the effects were unimpressive and the MDD subjects were specifically recruited to have diurnal variation in their symptoms, whereas the CFS subjects were not.

Cognitive function

We report several statistically significant differences in neuropsychological performance between CFS and healthy control subjects, on:

verbal fluency, CANTAB reaction time, psychomotor speed (DSST) and AVLT measures of immediate recall and recognition. These findings are very much in keeping with previous reports, which have also revealed objective evidence for impairments in verbal fluency (Krupp *et al.* 1994) and other executive tasks (Grafman *et al.* 1993; Ray *et al.* 1993; Wood *et al.* 1994); reaction time (Smith *et al.* 1996; Marshall *et al.* 1997; Vollmer-Conna *et al.* 1997); psychomotor speed (Smith *et al.* 1996; Michiels *et al.* 1997); and in various measures of attention and memory (Grafman *et al.* 1993; McDonald *et al.* 1993; Sandman *et al.* 1993; Krupp *et al.* 1994; Schmaling *et al.* 1994; Cope *et al.* 1995; DeLuca *et al.* 1995; Marcel *et al.* 1996; Smith *et al.* 1996; Marshall *et al.* 1997; Wearden & Appleby, 1997; Johnson *et al.* 1998; Michiels *et al.* 1998). The effects are modest and show little differential impairment on different test categories. A parsimonious explanation is that of a generalized impairment in information processing, perhaps attributable to low arousal or, given that the slower reaction times in our CFS subjects were attributable to movement rather than reaction latency, a difficulty in the execution of activity.

We found some statistically significantly greater impairments in MDD compared with CFS subjects, on measures of psychomotor speed (DSST) and memory. These results differ from those of the few previous comparisons, which have failed to find such differences (Schmaling *et al.* 1994; Cope *et al.* 1995; DeLuca *et al.* 1995; Marshall *et al.* 1997; Vollmer-Conna *et al.* 1997). We suspect that different outcomes depend upon the exclusion of CFS patients with a current depressive illness and the inclusion of more severe MDD cases. The similar degree of fatigue and motor impairment in our CFS and MDD patients suggests that the cognitive differences are not simply attributable to non-specific effects of illness severity.

Motor function

The shorter length of time that CFS subjects sustained a hand grip in the right (dominant) hand than healthy controls has not been previously reported, as far as we are aware. Although we cannot definitely state that these differences are not attributable to loss of muscle power (e.g. due to disuse), isometric muscle strength is generally normal in CFS (Lloyd *et al.*

1991; Kent-Braun *et al.* 1993; Blackwood *et al.* 1998) and it is parsimonious to link these results to the complementary findings of increased effort perception in these previous studies. The mean of three maximal voluntary contractions was strikingly lower in CFS subjects than in the healthy controls, being similar to those with MDD. Thus, patients with CFS have motor problems that are as severe as those found in MDD but a lesser degree of cognitive impairment.

Diurnal variation

There is only partial support for our differential diurnal variation hypothesis – i.e. improvement in MDD and worsening in CFS as the day wears on. The MDD patients' performances on cognitive and motor tasks do tend to objectively improve, as other have previously shown (Moffitt *et al.* 1994; Porterfield *et al.* 1997), but these improvements are not statistically different from those in CFS patients. There is certainly no consistent diurnal worsening in function in CFS as compared to MDD. Nonetheless, the fact that symptoms and task performance in CFS do not generally fluctuate diurnally, whereas they clearly can in MDD, suggests that there are neurobiological differences between the disorders despite many similarities in aetiological factors and symptoms. This is unlikely to be simply a matter of severity as our subjects with CFS performed as poorly as our MD subjects on many measures.

Implications

We have recently advanced an hypothesis that CFS may be primarily attributable to a failure in effort mobilization that is most evident on 'effortful' or controlled motor or cognitive activity (Lawrie *et al.* 1997b). Others have had similar ideas (Joyce *et al.* 1996). On self-rating of fatigue, and on objective measures of motor performance, patients with CFS and severe depressive illness were similar. Given the powerful evidence that retardation of motor function is a key feature of severe depressive illness (Parker & Hadzi-Pavlovic, 1996), this emphasis on motor performance is something that the conditions share. Why they do and what the underlying mechanisms are remain uncertain.

In regard to cognitive function, however, the two groups of patients studied in this report

show clear differences that suggested a more profound impairment of function in patients with severe depression. CFS subjects did tend to perform relatively more poorly than healthy controls on 'harder' tasks with greater demands on information processing capacity. Effortful cognition is also compromised in MDD (Cohen *et al.* 1982; Austin *et al.* 1992; Lawrie *et al.* 1997b), but the impairments at rest are much greater. CFS and MDD patients differ importantly in the impact of an exercise stressor upon neuropsychological performance (Blackwood *et al.* 1998).

Our observations accord with early reports of objectively mild but subjectively severe cognitive deficits in CFS (Millon *et al.* 1989; Altay *et al.* 1990; Ray *et al.* 1993). These were often interpreted as evidence of exaggerated complaints in CFS, as were early reports of increased effort perception, and usually attributed to personality difficulties (Buckley *et al.* 1999). To us, it is just as likely that subjective reports reflect processing requirements and objectively impaired neuropsychological function in CFS.

In this report, there are important similarities and differences between CFS and MDD, as we have found in studies of neuroendocrine function (MacHale *et al.* 1998) and with Single Photon Emission Tomography (MacHale *et al.* 2000). CFS and MDD may have similar provoking factors and an important overlap in the motor domain. If motor disturbance is primary, as CFS patients typically regard it, we still do not understand why that has different consequences for cognition in CFS from that in severe depression. Alternatively, psychomotor retardation in MDD may be associated with a less reversible impairment of cognitive function than that in CFS. Fatigue needs to be studied in a range of depressed patients before we can be confident that the crossover of impairment from the motor to the cognitive domain is as specific to CFS as it currently appears to be.

We thank the Scottish Office for financial support, Cathy Murray for technical assistance, local physicians for help in recruiting patients, and the subjects themselves for their time and interest in the study.
