

A Depolarization Ratio Anomaly Detector to identify icebergs in sea ice using dual-polarization SAR images

Armando Marino, *Member, IEEE*, Wolfgang Dierking, Christine Wesche.

ABSTRACT

Icebergs represent hazards to maritime traffic and offshore operations. Satellite Synthetic Aperture Radar (SAR) is very valuable for the observation of polar regions and extensive work was already carried out on detection and tracking of large icebergs. However, the identification of small icebergs is still challenging especially when these are embedded in sea ice. In this work, a new detector is proposed based on incoherent dual-polarization SAR images. The algorithm considers the limited extension of small icebergs, which are supposed to have a stronger cross polarization and higher cross- over co-polarization ratio compared to the surrounding sea or sea ice background.

The new detector is tested with two satellite systems. Firstly, RADARSAT-2 quad-polarimetric images are analyzed to evaluate the effects of high resolution data. Subsequently a more exhaustive analysis is carried out using dual-polarization ground detected Sentinel-1a Extra

Wolfgang Dierking is also with the Arctic University of Norway, Hansine Hansens veg 18, 9019 Tromsø

Wide swath images acquired over the time span of two months. The test areas are on the East Coast of Greenland, where several icebergs have been observed.

A quantitative analysis and a comparison with a detector using only the cross polarization channel is carried out exploiting grounded icebergs as test targets. The proposed methodology improves the contrast between icebergs and sea ice clutter by up to 75 times. This returns an improved probability of detection.

I. INTRODUCTION

Synthetic Aperture Radar (SAR) provides images of the microwave reflectivity of the Earth's surface. SAR instruments are highly valuable for monitoring polar regions since they do not rely on solar illumination and can operate almost independently of cloudiness [1]. Hence, they are optimal for iceberg monitoring from space. In this paper, we discuss a new method to detect icebergs by combining SAR images acquired in co-polarization (HH) and cross-polarization (HV), hence considering that the radar signal obtained from icebergs is in most cases dominated by volume scattering and/or multiple reflections, whereas signal characteristics from open water and saline sea ice are mainly determined by surface scattering [2], [3], [4].

The Greenland ice sheet loses mass due to melting and to accelerated ice flow. This dynamic thinning has been monitored over the entire ice sheet using repeated data acquisitions from satellite altimetry [5]. The thinning is higher at the margins of the marine-terminating glaciers, the birthplaces of icebergs [6].

One of the largest tidewater glaciers in Greenland is the Helheim Glacier in southeastern Greenland. Calving occurs year-round at the 6 km wide calving front into Helheim Fjord, which is a lateral branch of Sermilik Fjord. Due to the highly crevassed front of the Helheim

18 glacier, only a few tabular icebergs were observed to calve. Most calving events create
19 smaller icebergs that topple in- or outward [6]. For the study presented in this paper, we
20 selected Helheim Glacier as one of our test sites.

21 In SAR images, icebergs are often (but not always) visible as bright targets. Under freezing
22 conditions in calm open water or young undeformed sea ice, the radar signature contrast
23 between icebergs and the background clutter (i. e. the radar reflectivity of open water or
24 smooth sea ice) is high enough for an automated detection using single-polarization SAR
25 imagery [7], [8], [9]. Since smaller icebergs that calve from Helheim Glacier or any other
26 marine-terminating glacier in Greenland or Antarctica tend to topple in open water, their
27 backscattering characteristics change because the ice surface is wet or covered by frozen sea
28 water. If the iceberg capsizes, the surface may consist of a layer of marine ice that formed
29 the bottom layer before the berg calved. In this case, the contrast between iceberg and clutter
30 is very small, so that an automated detection of icebergs using single-pol imagery is nearly
31 impossible [7]. The success of detection depends also on the spatial resolution of the SAR
32 image and the areal extension of the iceberg. Icebergs are more difficult to identify if they
33 cover only a few image pixels, and cannot reliably be detected if their size is close to or even
34 smaller than the image resolution.

35 A hemispheric wide systematic iceberg detection is not existent, but studies focusing on
36 different regions were published. E.g., Abramov [10] reports on iceberg observations in the
37 Barents Sea carried out from ships and during reconnaissance flights that were conducted by
38 the Russian Arctic and Antarctic Research Institute (AARI) between 1933 and 1990. The
39 Danish Meteorological Institute (DMI) investigated the iceberg frequencies in open waters in
40 the Disco Bay (West Greenland) and Scoresbysund (East Greenland) using more than 8000
41 SAR scenes (most of them acquired after 2009). For the automated detection, they applied

42 a constant false alarm rate technique [11]. A maritime monitoring service for the Canadian
43 Arctic is offered by C-CORE, a Canadian research and development cooperation. They
44 have been developing software for iceberg detection and classification in SAR images taking
45 advantage of the dual- and quad-polarization capabilities of modern SAR systems. However,
46 details about their method are not provided [12]. Andres et al. [13] present a different
47 approach of detecting icebergs. Here, inverted echo sounders equipped with pressure sensors
48 were installed in Sermilik Fjord between August 2011 and September 2012. These sounders
49 are able to distinguish iceberg and sea ice by their draft [13]. Although this method is
50 spatially limited to the locations where the instruments were deployed, and does not detect
51 bergs passing through the spatial gaps between the sounders, it is useful to identify icebergs
52 for validating the detection algorithms developed for SAR images.

53 The paper is organized as follows. Section I provides a brief introduction on iceberg
54 detection and polarimetric radar. Section II introduces the new detector that is tested with
55 RADARSAT-2 and Sentinel-1 data in Section III and IV respectively.

56 *A. Iceberg Detection*

57 An ordinary approach to iceberg detection considers the exploitation of algorithms previ-
58 ously developed for ship detection. More specifically, several of these methodologies aim
59 at discriminating between targets and background clutter performing a statistical test on the
60 image brightness. The problem of selecting the threshold can be solved using the Neyman-
61 Pearson lemma on the probability of detection (P_d) or false alarms (P_f) [14]. The most
62 common methodology is called constant false alarm rate (CFAR) and set a threshold that is
63 supposed to keep P_f constant [15], [16], [17], [18], [19], [20], [21], [22], [23]. CFAR algo-
64 rithms are generally (but not necessarily) applied to single intensity images. When only a

single image is available, one important advantage of using a CFAR methodology, compared to setting a global threshold, is that the detection task becomes more automatic. The CFAR is capable of setting the threshold locally by extracting the clutter statistics. However, it is important to keep in mind that the performance of a CFAR is dependent on the suitability of the statistics employed to fit the clutter. A disadvantage of CFAR on single intensity image is that they do not perform any image enhancement based on some physical rational. To compensate for this the CFAR algorithms can be applied on one image that has been previously enhanced using different polarimetric channels (as in this work).

The proposed detector makes use of two differently polarized channels. The use of different polarizations is expected to add information because different targets are supposed to exhibit different polarimetric behaviors [24]. Therefore, the differences between clutter and targets can be magnified based on the responses at different polarizations, which helps detection or classification [25], [26], [27], [28], [29], [30], [31].

In this work, we focus on the particularly challenging condition of medium and small icebergs embedded in sea ice. Although the detection of icebergs of several kilometers size is routinely done, there are still issues in identifying icebergs smaller than a few hundred meters, especially when embedded in sea ice [4], [32], [3], [2]. To be in accordance with the detection jargon, in the following the sea ice background will be referred as clutter. Sea ice is expected to exhibit a high level of clutter (i.e. bright background) in several cases. This has two main drawbacks for single polarization detectors:

- (1) If the algorithm sets the threshold globally, a very bright clutter can trigger detections. This introduces false alarms.
- (2) If the algorithm sets the threshold locally (based on the background level) the high clutter brightness returns very high thresholds that may miss icebergs. This introduces missing

89 detections.

90 By using different polarizations, we want to add more physical information that can in-
91 crease the contrast between targets and clutter.

92 *B. Polarimetric Radar*

93 In the following, a very brief introduction to polarimetry is presented, with the mere pur-
94 pose of introducing the symbolism used in the following. A single target has a fixed po-
95 larization in time/space and we can characterize it using the scattering (Sinclair) matrix or
96 equivalently a scattering vector \underline{k} [24]. This is normally represented as

$$[S] = \begin{bmatrix} HH & HV \\ VH & VV \end{bmatrix}, \quad (1)$$

97 where H stands for linear horizontal and V for linear vertical (therefore the HV image is ob-
98 tained transmitting a linear vertical polarization and receiving the linear horizontal one). The
99 diagonal elements are often referred to as co-polarization channels and the off-diagonal are
100 the cross-polarization channels. The full scattering matrix can be acquired only with quad-
101 polarimetric data. When only two polarization channels are available, the mode is referred
102 to as dual-polarimetric if the channels are coherent (i. e. their complex correlation coeffi-
103 cient can be determined) or dual-polarization if data acquisition is incoherent. The targets
104 observed by a SAR system are often distributed and composed of different objects. For this
105 reason, each pixel of such distributed targets may have a specific polarimetric behavior. In
106 order to extract meaningful information regarding the polarimetric behavior averaging (or
107 filtering) is required [24]. This is also valid if only the intensity of the polarimetric channel
108 is available.

109 Unfortunately, currently radar satellites (including RADARSAT-2, ALOS-2, TanDEM-X

and Sentinel-1) can only provide very large swaths with dual-polarization data [33]. This is a limitation for applications as iceberg detection, since the use of large swaths is fundamental. For this reason, we propose a detector combining the HH- and HV-polarized intensity data. On the other hand, it is expected that the use of quad-polarimetric data can improve the detection performance. In the future, the availability of polarimetric images with large swaths may provide significant improvements in iceberg detection for operational purposes.

II. DUAL-POL RATIO ANOMALY DETECTOR (DPOLRAD)

A. *Dimensionless detector*

In this section, a new algorithm is proposed for the detection of small icebergs embedded in sea ice. The design is based on the idea of producing a methodology that could be eventually used operationally. At the moment, there are two clear constraints for operational algorithms:

- (1) Data availability: we need to exploit acquisition modes able to cover large areas (e.g. Sentinel-1 Extra Wide). Therefore, only dual-polarization incoherent HH/HV or VV/VH images can be used.
- (2) Processing burden: an operational detector should be fast and not excessively reliant on high processing burden. For this reason, we tried to develop an algorithm that is efficient and fast.

The algorithm is based on the observation that icebergs or thick/deformed sea ice exhibit a different polarimetric behavior compared to thinner sea ice. Specifically, the cross polarization channel and the ratio between cross- and co-polarizations (here referred as depolarization ratio) increase. There are several physical explanations for such observations [4]. Icebergs are made of fresh water ice that in dry conditions has a much lower dielectric

133 loss compared to sea ice. This allows for a much larger penetration of electromagnetic waves
134 in the iceberg (depending on the wavelength), which may lead to volume scattering or scat-
135 tering from randomly oriented parts inside the ice body (e.g. ice lenses or pipes). Another
136 explanation is the presence of multiple reflections (specifically even-bounces) with random
137 orientations. Such multiple reflections can occur as double-bounce with the clutter surface
138 or the presence of cracks and structures in the ice body (e.g. pinnacles). In order to have
139 an increase of the cross-channel, the corner of the double-bounce has to have an orientation
140 (as seen by horizontally or vertically polarized waves) different from horizontal or vertical.
141 Interestingly, this explanation does not require the dielectric constant to be very low (i.e. dry
142 conditions) and could be applied to wet conditions as well. This is because in wet conditions
143 the wave penetration is very limited and the icebergs appear as a set of oriented surfaces.

144 The fact that the two previous explanations cover two different wetness conditions, in
145 theory, provides the detector with a wider applicability. As a final remark, it is interesting to
146 notice that the same observation can include two physical processes that are very different
147 from the polarimetric point of view. Random volume scattering is an incoherent process
148 with a low degree of polarization, while oriented even-bounce is highly coherent. This is a
149 clear indicator that the exploitation of polarimetric data is advantageous not just to detect the
150 icebergs, but also to retrieve geophysical parameters and/or information about the scattering
151 and reflection processes taking place.

152 Two boxcar filters are applied over the HV and HH intensity images, exploiting two dif-
153 ferent window sizes: a smaller test window w_{test} and a larger training window w_{train} . Details
154 on the dimensions are provided in next section. The detector, which we call DPoIRAD, can

be written as:

$$\Lambda = \frac{\langle |HV|^2 \rangle_{test} - \langle |HV|^2 \rangle_{train}}{\langle |HH|^2 \rangle_{train}} > T_{\Lambda}. \quad (2)$$

where $\langle \rangle_{test}$ and $\langle \rangle_{train}$ are the spatial averages using the test and training windows respectively and T_{Λ} is a threshold.

To gain some physical understanding of the proposed formula, some mathematical manipulations can be carried out. If the averages are expressed explicitly the following equation can be derived (the mathematical manipulations are reported in the Appendix):

$$\Lambda = \rho_{ring} \frac{1 + c}{R\rho^{-1} + cR HV^{-1}} - \rho_{train} \quad (3)$$

ρ stands for cross-over-co polarization ratio, in the following defined as depolarization ratio. The subscript is used to identify if the ρ is estimated in the ring area or the training area. The ring area is composed by the pixels of the training area that do not belong to the test area (e.g. a ring of pixels around the test area). As mentioned previously, this observable is sensitive to the presence of volume scattering or orientated structures. $R\rho$ is the ratio between the ρ inside the test area over the one in the ring around the test area (i.e. $R\rho = \frac{\rho_{test}}{\rho_{ring}}$). RHV is the ratio of the HV intensity in the test area over the ring area (i.e. $RHV = \frac{\langle |HV|^2 \rangle_{test}}{\langle |HV|^2 \rangle_{ring}}$). c is a factor such that $N_{train} = cN_{test}$ where N_{train} and N_{test} are the number of pixels inside the training and test windows. ρ_{ring} and ρ_{train} are the depolarization ratios in the ring and the entire training windows respectively.

Analyzing some special condition is possible to gain insights into the nature of the detector:

(1) It is easy to prove that Λ is equal to zero if the depolarization ratio and the HV intensity do not change between the ring and the test area. This is because $\rho_{ring} = \rho_{train}$ and

175 $R\rho = RHV = 1$. As a consequence, homogeneous areas will provide a Λ that is equal
176 to zero.

177 (2) If and only if the depolarization ratio and the HV intensity are higher in the test area than
178 in the ring, then Λ becomes very large. An easy way to test this is by considering the
179 limit of $R\rho$ and RHV going to infinity:

$$\lim_{\substack{R\rho \rightarrow \infty, \\ RHV \rightarrow \infty}} \Lambda = \rho_{ring} \frac{1+c}{0+c0} - \rho_{tot} = \infty \quad (4)$$

180 Clearly, $R\rho$ and RHV will never reach infinity in real data due to the noise level (i.e. the
181 values in the ring areas cannot be exactly zero).

182 (3) Finally, if the volume or multiple reflections decrease drastically from the ring to the test
183 area (e.g. a pool of open water in multi-year sea ice), then Λ becomes negative. A way
184 to see this is by analyzing the limit of Λ when $R\rho$ and RHV go to zero.

$$\lim_{\substack{R\rho \rightarrow 0, \\ RHV \rightarrow 0}} \Lambda = \rho_{ring} \frac{1+c}{\infty+c\infty} - \rho_{tot} = -\rho_{tot} \quad (5)$$

185 To summarize, if an iceberg of the right size enters the test window, the value of Λ in-
186 creases triggering a detection. However, if the iceberg or sea ice is significantly larger than
187 the test window it will contaminate the training window not providing a sufficient anomaly
188 to trigger the detector. The size of the test area depends on the size of the iceberg to detect.
189 On the other hand, the size of the training area depends on the requirement we have in de-
190 tecting icebergs of a precise size. If the training window is much larger than the test window,
191 iceberg that are slightly larger than the test window will still be detected, because the iceberg
192 part that does not fit in the test window will be averaged out over the large training area. On
193 the other hand, with a smaller training area, we would be more selective on the maximum
194 size that the iceberg can have. Depending on the application (e.g. classification), this may

195 be important. At the moment, we are not too interested in fixing precisely the size of the
196 iceberg and therefore we have a training area that is rather large.

197 As a final remark, it is interesting to notice that the same derivations can be done using
198 the VV/VH mode, where the depolarization ratio becomes the ratio between the intensity
199 of VH over VV. The detectors exploiting the two different modes are based on the same
200 physical rational and therefore they are expected to have similar results. This is because HH
201 and VV have a rather similar scattering behavior on sea ice [34], [35] with some variations
202 that depend on the ice type. Also, icebergs are expected to scatter similarly in HH and VV,
203 depending on ice structure. In order to evaluate if one mode is preferred to the other, a
204 systematic analysis has to be carried out for different sea ice conditions and iceberg char-
205 acteristics. In this work, we concentrate on the HH/HV mode, since this is the Sentinel-1
206 preferred mode for observing sea ice and it is routinely acquired in the Arctic [36].

207 *B. Contrast enhancement*

208 Λ is large when there is an increase in volume or multiple reflections, equals to zero on
209 homogeneous targets and is negative if volume scattering or multiple reflections occur mainly
210 in the ring area but are of lower magnitude in the test window. Such detector is built as a ratio
211 between intensities and therefore it is scale invariant. This is a very valuable property for a
212 polarimetric indicator, however scale invariance may be disadvantageous for some detection
213 tasks. For instance, if the signal is very low and close to the noise floor, an increase in the
214 volume component that is small in absolute magnitude may return a large Λ . An easy way to
215 bypass this is giving the scale back by multiplying the detector by an intensity or magnitude
216 image. In this context, the cross polarization channel should to be preferred because it shows

217 a higher contrast between icebergs and clutter:

$$I = \Lambda \cdot \langle |HV|^2 \rangle \quad (6)$$

218 In the following, we denote this expression as "HV-DePolRAD". If a pixel of the HV in-
 219 tensity image presents an anomaly in volume or multiple reflections, then it is multiplied
 220 by a large number. If it presents a homogeneous area, then it is multiplied by zero and
 221 if it presents a decrease in volume or multiple reflections, then it becomes negative. This
 222 enhances the contrast between anomalies in volume or multiple reflections and clutter.

223 *C. Final remarks*

224 As mentioned previously, the window size defines the dimension of targets (icebergs or
 225 thick/deformed ice) that can trigger the detection. Clearly, we cannot be completely sure that
 226 the detected object is an iceberg or a right-sized block of thick/deformed sea ice. However,
 227 both typologies of ice may represent hazards for the navigation and therefore it may be
 228 beneficial to detect them both.

229 III. TEST WITH REAL DATA: RADARSAT-2

230 *A. Data Presentation*

231 In order to test the detector, real RADARSAT-2 and Sentinel-1 data are exploited. In this
 232 first section, results with quad-polarimetric Fine RADARSAT-2 acquisitions are presented.
 233 The latter are provided with a rather small swath width of around 25 km, therefore their use
 234 for operational purposes is restricted to strategic areas. The test presented here demonstrates
 235 the capabilities of the detector using image products with high spatial resolution. Moreover
 236 it is easier to identify icebergs visually and hence provide a mean of evaluating the detection

TABLE I

DETAILS ON FINE QUAD-POL RADARSAT2 DATA. TIME IS IN UTC.

Date (Time)	Location	Beam	Incidence angle	Ground range res.
27/12/2013 (09:06)	Helheim	FQ15	$\sim 35^\circ$	9.2 m to 8.8 m
21/02/2014 (20:05)	Helheim	FQ19	$\sim 39^\circ$	8.4 m to 8.1 m

performance. The following section deals with an exhaustive analysis of Sentinel-1 data that provides insights on actual operational conditions.

In order to increase the probability to observe icebergs, the data were acquired in the basin of the Helheim Glacier on the East Coast of Greenland. Helheim is one of the fastest calving glaciers and it finishes in a relatively long fjord, where the icebergs remain before they reach the open ocean. Moreover, the acquisitions were performed in winter, where it is expected that the fjord is covered by sea ice.

Figure 1.a and 2.a present the Pauli RGB images of the two scenes. The first exploits a FQ15 beam and it was acquired on the 27/12/2013. The second employs the FQ19 beam and it was acquired on the 21/02/2014. Table I presents the main characteristics of data exploited. Only a zoom of the second acquisition is shown here to provide a closer look at the detection masks near the melange margin.

Unfortunately, a ground survey of icebergs or thick/deformed ice is not available and we had to rely on visual inspection of the images. In particular, targets of interest were identified as bright regions in the HV channel of specific dimensions. Moreover, a shadow area in the far range and a bright rim in the near range was searched.

Fig. 1. Detection for the FQ15 27/12/2013 RADARSAT-2 dataset (Helheim, Greenland). (a) Pauli RGB image;
(b) Mask with the proposed detector.

253 B. Test of Detection

254 The proposed algorithm only requires the intensity of HV and HH polarization channels,
 255 therefore the polarimetric capability is not fully exploited here. The window sizes used are
 256 $w_{test} = [21, 21]$ and $w_{train} = [101, 101]$ pixels. These window size are selected in order to
 257 have a test window that is in between 100 m and 200 m of size and it is comparable with
 258 the following tests performed with Sentinel-1 data. Figure 1.b and 2.b present the detection
 259 masks for the two areas of interest. The detection mask was obtained using thresholds on
 260 the HV-DPolRAD set locally on large training windows. More details on how to set the
 261 threshold for the HV-DPolRAD are reported in the next section. We found that all the bright
 262 and isolated areas with a specific size seem to be detected (i.e. large bright areas are rejected).

263

264 In order to provide a comparison, two detectors that consider the HV intensity alone are

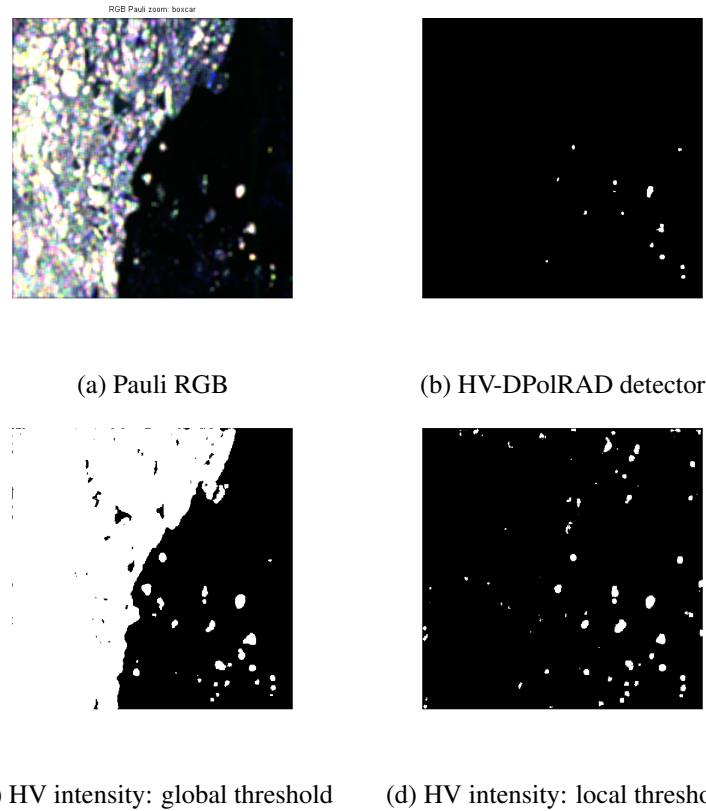

Fig. 2. Detection for the FQ19 21/02/2014 RADARSAT-2 dataset (Helheim, Greenland). (a) Pauli RGB image; (b) Mask with the HV-DPolRAD detector; (c) Mask with the HV intensity using CFAR: $P_f = 10^{-6}$; (d) Mask with the HV intensity with empirical threshold equal to 0.1.

presented in Figure 2. The first detector sets the threshold globally using an empirical value derived by the analysis of the histogram for the large region of sea ice. The second detector sets the threshold locally exploiting ring guards (as for a CFAR methodology). The theoretical pdf used to calculate the probability of false alarms P_f is a K-distribution and the value $P_f = 10^{-6}$ is used.

It is possible to observe that the intensity alone provides several false alarms. This is due to the fact that when the clutter background has a low backscattering, several small anomalies are detected. Additionally, if the statistics are not extracted locally, large portions of sea ice are detected.

TABLE II

DETAILS ON EW SENTINEL-1 DATA.

Location	Modes	Incidence angle range	Ground range res.	Swath
East Greenland	EW HH/HV detected	18.9° to 47°	20 × 40 m	400 km

IV. TEST WITH REAL DATA: SENTINEL-1

A. *Presentation of data*

In this section, the algorithm is tested using Sentinel-1 Extra Wide (EW) Swath dual-polarization images. The later provide an interesting opportunity for operational use based on their large coverage and smaller data size.

The ESA Hub archive was searched downloading images that could suite the detection exercise. We selected as test area the East Coast of Greenland, in the Fram Strait where the glaciers Helheim and Kangerdlugssuaq calve. Moreover, we selected acquisitions in the months from March to April 2015, since this should allow to monitor a relatively large amount of icebergs that are still embedded in sea ice (if not too far from the coast). Interestingly, we downloaded 31 EW dual-pol Ground Detected (GRD) acquisitions from the 1st of March to the 30th of April, with an average of around one image every two days. This remarkable repeat time allows to monitor the temporarily grounded icebergs, which can be easily used as validation targets.

Table II summarizes some characteristics of all the EW Sentinel-1 images exploited [37]. More details on acquisition times are provided in a following table.

Figure 3 shows the location of three of the 31 acquisitions to provide an idea of the geographical area of interest and coverage.

Fig. 3. Three Sentinel-1 EW acquisitions overlaid on Google Earth.

292 *B. Visual inspection*

293 In a preliminary analysis, few of the HH and HV magnitude images are shown. EW
 294 images have a very large coverage and presenting them in their entirety would make the
 295 identification of icebergs very challenging. For this reason, only small crops of the entire
 296 images are shown in the following.

297 Figure 4 and 5 present the magnitude of HH and HV for 6 different acquisitions. The
 298 images are in radar coordinates, therefore each axes represent the pixel coordinate. The
 299 first three represent an area just outside the basin where the Kangerdlugssuaq glacier calves.
 300 From the time series, it is possible to identify several bright points that move very slowly.
 301 Interestingly, some of these points cannot be detected in the HH channel, showing the im-
 302 portance of the cross polarized channel for iceberg detection. In particular, 10 points of the
 303 visually analyzed images appear to be stable (they are less visible in the April acquisition,
 304 maybe due to melting conditions).

305 A second set of images is considered to test the capability of the new detector to reject
 306 edges (the ice marginal zone) and detect icebergs embedded in bright sea ice clutter.

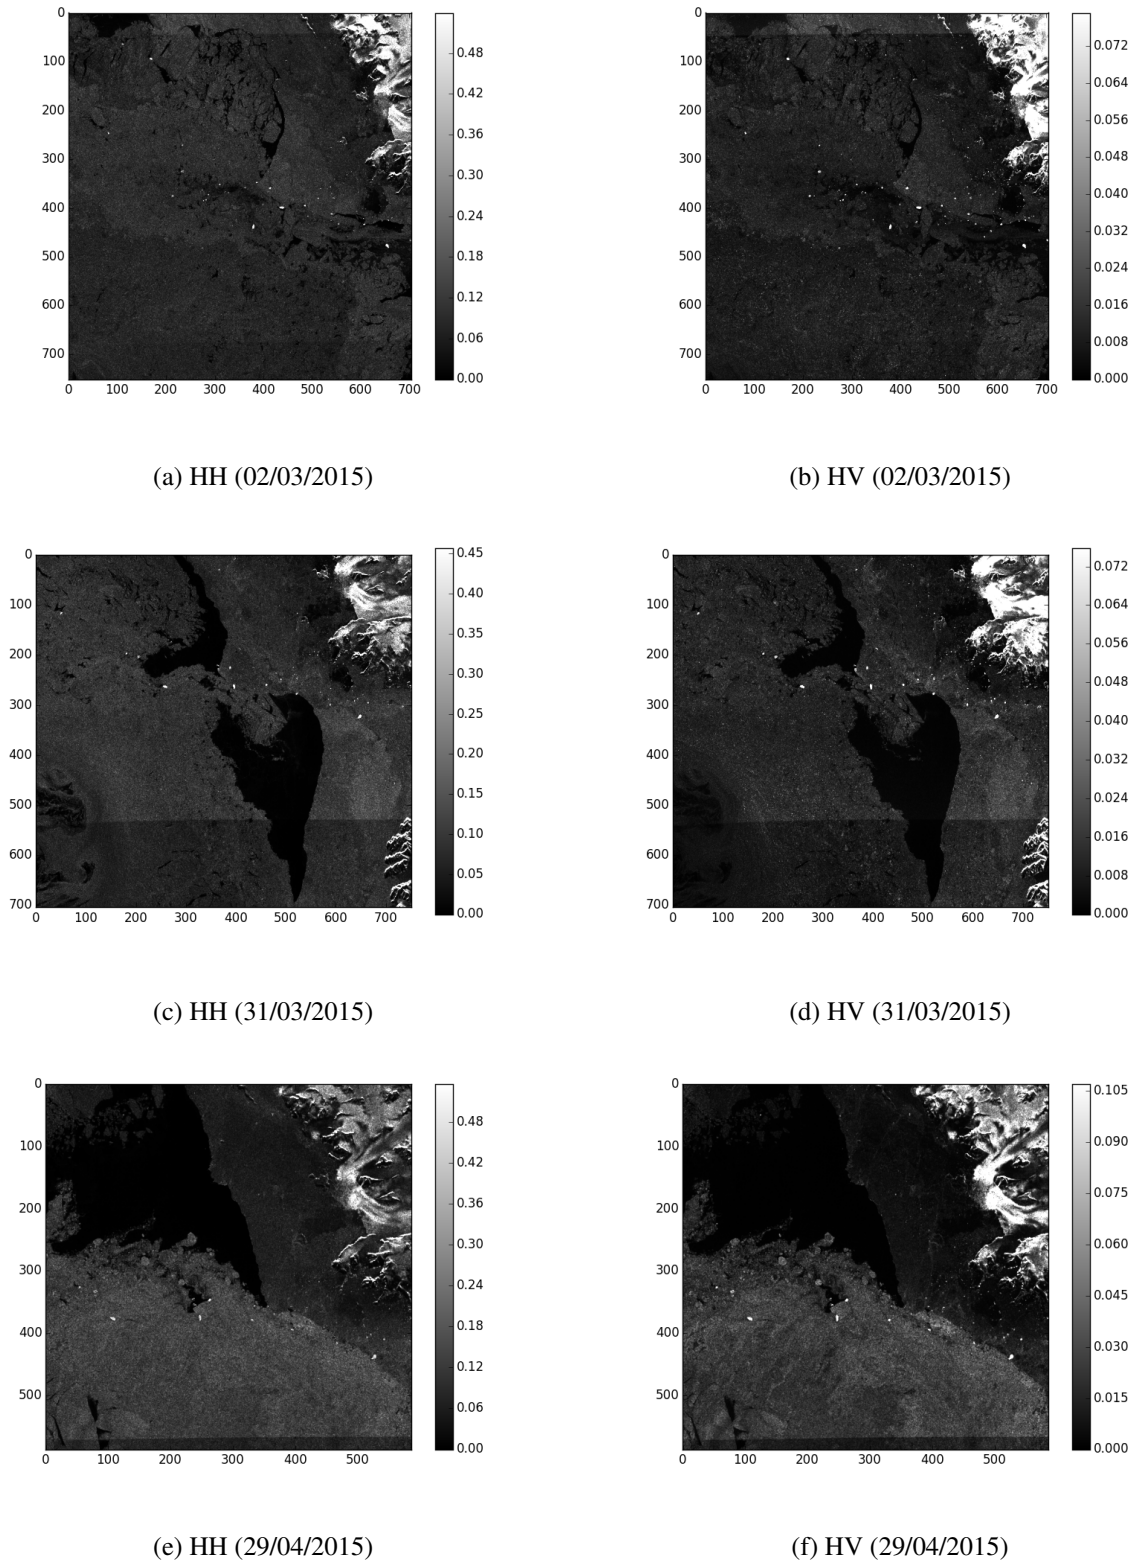

Fig. 4. Magnitude of HH and HV channels, Sentinel-1 EW (Kangerdlugssuaq, Greenland). (a) HH (02/03/2015); (b) HV (02/03/2015); (c) HH (31/03/2015); (d) HV (31/03/2015); (e) HH (29/04/2015); (f) HV (29/04/2015). Boxcar filter: 3×3 pixels.

(e) HH (30/04/2015)

(f) HV (30/04/2015)

Fig. 5. Magnitude of HH and HV channels, Sentinel-1 EW (Fram Strait, Greenland). (a) HH (03/04/2015); (b) HV (03/04/2015); (c) HH (10/04/2015); (d) HV (10/04/2015); (e) HH (30/04/2015); (f) HV (30/04/2015).

Boxcar filter: 3×3 pixels.

307 *C. Contrast enhancement*

308 The capability of the HV-DPolRAD to enhance the contrast between icebergs and sea ice
 309 is described in the following. The test window considers 3×3 pixels, while the training
 310 window is 63×63 pixels. The results for the 6 images are shown in Figure 6. The scaling
 311 used for these images is exactly the same as exploited for the HV magnitudes. The images
 312 appear darker, because the sea ice clutter is strongly reduced. In these images, when the
 313 DPolRAD is negative (i.e. reduction of volume or multiple reflections) the HV-DPolRAD is
 314 set to zero. On the other hand, bright isolated points remain bright. In order to have a better
 315 look at the increase in contrast, in Figure 7 the three final acquisitions are used to obtain 3D
 316 plots of the HV magnitude and the HV-DPolRAD (i.e. enhanced HV magnitude).

317 From the 3D plots it is evident that the clutter background is reduced and the contrast
 318 enhanced. It should be noted that the scaling between the 3D plots changes. It can be
 319 observed that several peaks are stretched upward, while the clutter is reduced. These plots are
 320 shown only for qualitative analysis and in the following a quantitative analysis is provided.

321 *D. Detection masks*

322 The detection masks obtained with the HV-DPolRAD are here compared with a Cell-
 323 Averaging Constant False Alarm Rate (CA-CFAR) detector. The latter extract the mean in
 324 the training window and sets the threshold equal to the mean multiplied by a factor. The
 325 factor for the CA-CFAR is selected equal to 5, since in several works, including [15], this
 326 factor has revealed to provide a good compromise between detection and false alarms. The
 327 threshold of the HV-DPolRAD is set locally (over frames of 200×200 pixels) using a CA-
 328 CFAR approach employing a factor of 50. A higher factor is used because the background is
 329 strongly reduced and we can benefit of a much higher contrast. The advantage of applying

The horizontal axes are pixel coordinates and the vertical axis is pixel amplitude.

330 large frames instead of ring windows is that the former allow to have more clutter samples
331 that are different from zero. In this preliminary approach, the pixels equal to zero or above
332 a high empirical threshold are excluded to calculate the mean clutter. In the future more
333 elaborated methods to set the threshold will be investigated. This includes the attempt to
334 derive an analytic expression for the pdf of HV-DPolRAD.

335 For comparison, the CA-CFAR is applied on the HV-intensity image. Unfortunately, if we
336 want to exploit an exact CFAR using a K-distribution (as done in the test with RADARSAT-
337 2), the integral of the probability of false alarm has to be inverted numerically. This brings
338 a computational burden that may be unacceptable for operational purposes with Sentinel-1
339 EW due to the very large amount of data to process. For this reason, the Cell-Averaging
340 CFAR (CA-CFAR) is used and the solution of the numerical integral with a K-distribution
341 is not attempted. This is also the reason why the CA-CFAR is so diffuse in operational
342 algorithms. On the other hand, it is important to keep in mind that the CA-CFAR is only an
343 approximation for the actual CFAR, which requires more powerful models to characterize
344 the underlying statistics.

345 The images from the Kangerdlugssuaq glacier are analyzed first (Figure 8). The proposed
346 algorithm is able to detect areas with possible presence of icebergs. They cluster roughly
347 along a line and except for orientations (due to the different orbits), they preserve their dis-
348 tances in the two month time span. Compared to the CA-CFAR, the proposed detector is
349 more robust against false alarms. These occur mostly in boundary regions between dark and
350 bright clutter.

351 In the second series of images (Figure 9), the HV-DPolRAD seems again able to detect
352 points that are candidate for icebergs. Some of these points appear in different images of the
353 time series and therefore they could be attributed to grounded icebergs. These regions were

354 selected because the sea ice clutter is brighter and therefore it represents a harder challenge
355 to the detectors. Interestingly, the HV-DPolRAD is able to detect points that are missing in
356 the CA-CFAR detection mask. This is thanks to the enhanced contrast between sea ice and
357 icebergs.

358 In the future, more work will be dedicated at understanding the potentialities of proposed
359 algorithms for operational purposes. Among other analysis, points as time burden and opti-
360 mal threshold or windows selection will be tackled.

361 *E. Quantitative analysis*

362 In this final section, a quantitative analysis is performed. In particular, grounded icebergs
363 can be used as validation targets. These were found not only near the basins where the
364 Helheim and Kangerdlugssuaq glaciers calves, but also in other areas around the coastline.
365 To extend this dataset, icebergs are searched in other areas of the dataset as well. Another
366 indicator used to reveal the presence of icebergs is the closeness to a dark area. This can be
367 produced by radar or wind shadow or it may be due to the fact that grounded icebergs break
368 the surrounding sea ice and produce pools (or leads) of open water which may eventually be
369 covered by smooth young ice under cold conditions.

370 The values for iceberg brightnesses used in the analysis are the ones representing the
371 maximum inside the bright area visually identified as iceberg after the smoothing with the
372 test window. These are the pixels that will contribute more for achieving the detection.
373 The clutter brightnesses are estimated in each acquisition separately, using very large areas
374 containing sea ice. In this areas, the pixels previously identified as icebergs are removed to
375 avoid contamination of the clutter. Evaluating the clutter separately in different acquisitions
376 allows to analyze different ice conditions separately without losing temporal information.

377 Tables III and IV collect results for the March and April acquisitions respectively. Each
 378 row of the table represents an acquisition. The two lines in each row indicates from which
 379 image (specified in the squared bracket) the value is taken.

380 The values for the HV magnitude are listed as well to provide a comparison. The tables
 381 report the minimum, maximum and mean contrast in each acquisition. In each row, the
 382 number on top represents the value for the HV magnitude and the number on bottom is for
 383 the HV-DPolRAD. It is interesting to evaluate the amount of clutter reduction compared to
 384 HV-intensity images, for the purpose of using the HV-DPolRAD images as an aid to visual
 385 inspection by analysts. The sixth column of the tables presents a comparison for the number
 386 of detected icebergs. Unfortunately, without ground surveys it is not possible to obtain any
 387 meaningful estimation of the probability of false alarms (since we do not know if a detection
 388 is genuine). The final column presents the number of icebergs used in each scene.

389 It is apparent that the contrast is highly improved and the clutter is strongly reduced. To
 390 visualize this result, Figure 10 plots the ratios between the HV-DPolRAD and HV mean con-
 391 trasts and sea ice clutter levels. In the plot these are called "factor of improvement" since they
 392 tell how many times the contrast is increased and the clutter level is reduced. Specifically, the
 393 red curve was obtained from $\frac{meanC(HVDPolRAD)}{meanC(HV)}$, while the blue curve was calculated using
 394 $\frac{Clutter(HV)}{Clutter(HVDPolRAD)}$. In March (colder conditions) the improvement in contrast seems to be
 395 generally higher than 60 times (with few cases higher than 100). In April, the improvement
 396 in contrast is more variable and probably depends on melting conditions that makes icebergs
 397 less visible. In average, the factor of improvement is 75. Regarding the reduction of sea ice
 398 clutter, this seems to be always higher than 20 in both months and average at approximately
 399 35.

400 The probability of detection for the HV-DPolRAD is always equal to one (all icebergs

401 detected) at exception of two scenes where P_D is 0.99 and 0.96. This result is due to the fact
 402 that in these tests we only used pixels where we have confidence of having an iceberg. It is
 403 likely that our selection left out several challenging icebergs simply because we could not
 404 spot them in the images. For this reason, the reported results for P_D should only be taken
 405 as indicative, for the mere sake of comparison with the HV single channel. Even in this
 406 simplified test, it can be observed that the HV-DPolRAD provides better detection compared
 407 to the cross-pol channel alone. This is expected considering the improvement in contrast.

408 V. CONCLUSIONS

409 In this work, we proposed a new detector based on a new polarimetric indicator, the Dual-
 410 Polarization Ratio Anomaly Detector (DPolRAD). The algorithm is focused on small ice-
 411 bergs or thick/deformed ice-blocks and it is based on the combination of cross- and co-
 412 polarized SAR images. In the development of the method we assumed that small icebergs
 413 are contained in a limited area and they have a volume or multiple reflections contribution

that is higher compared to the surrounding sea or sea ice background. The DPolRAD is used to develop a detector called HV-DPolRAD, aimed at improving the contrast between icebergs and sea ice. The latter could also be used by ice analysis to aid visual inspection.

The detector was tested with RADARSAT-2 quad-polarimetric data and Sentinel-1 Extra Wide swath HH/HV images. We selected 31 Sentinel-1 images acquired in the East Coast of Greenland in March and April 2015. The dense time series allows to identify grounded icebergs that can be used for validation purposes.

It was observed that the HV-DPolRAD is able to improve the contrast between icebergs and sea ice compared to the HV channel alone. The improvement is in average equal to approximately 75 times. Additionally, the sea ice clutter is reduced by a factor that is in average equal to 35. The quantitative analysis showed also improved probability of detection compared to a CA-CFAR, with the HV-DPolRAD be able to detect all the identified icebergs except for two scenes.

In the future, more work will be dedicated to evaluate the potentialities of the proposed algorithms for operational use. Among other analyses, time burden and comparison of methodologies for optimal threshold and windows selection will be tackled.

APPENDIX

In this section the derivation of the formula used to gain a physical understanding of the detector is provided. We start from the expression:

$$\Lambda = \frac{\langle |HV|^2 \rangle_{test} - \langle |HV|^2 \rangle_{tr}}{\langle |HH|^2 \rangle_{tr}} \quad (7)$$

If $\frac{\langle |HV|^2 \rangle_{tr}}{\langle |HH|^2 \rangle_{tr}} = \rho_{tr}$ we can rewrite Λ as:

$$\Lambda = \frac{\langle |HV|^2 \rangle_{test}}{\langle |HH|^2 \rangle_{tr}} - \rho_{tr}$$

The averaging can be represented as the sum of the pixels inside an averaging window, divided by the total number of pixels considered. This is $\langle |HV_i|^2 \rangle_{test} = \frac{1}{N_{test}} \sum_{i=1}^{N_{test}} |HV_i|^2$. Additionally, the training window is composed by the test window plus a ring of pixels around the test window. Applying these two manipulations to the previous formula we obtain:

$$\begin{aligned} \Lambda &= \frac{\sum_{i=1}^{N_{test}} |HV_i|^2}{N_{test}} \frac{N_{test} + N_{ring}}{\sum_{i=1}^{N_{test}} |HH_i|^2 + \sum_{i=1}^{N_{ring}} |HH_i|^2} - \rho_{tr} \\ &= \frac{\sum_{i=1}^{N_{test}} |HV_i|^2}{\sum_{i=1}^{N_{test}} |HH_i|^2 + \sum_{i=1}^{N_{ring}} |HH_i|^2} \frac{N_{test} + N_{ring}}{N_{test}} - \rho_{tr}. \end{aligned} \quad (8)$$

If we define $N_{ring} = cN_{test}$ the equation can be written as:

$$\Lambda = \frac{1 + c}{\frac{\sum_{i=1}^{N_{test}} |HH_i|^2}{\sum_{i=1}^{N_{test}} |HV_i|^2} + \frac{\sum_{i=1}^{N_{ring}} |HH_i|^2}{\sum_{i=1}^{N_{test}} |HV_i|^2}} - \rho_{tr}$$

Going back with the representation with angular brackets and considering the definition of the depolarization ratio the following expression can be written:

$$\Lambda = \frac{1 + c}{\rho_{test}^{-1} + \frac{\langle |HH|^2 \rangle_{ring} N_{ring}}{\langle |HV|^2 \rangle_{test} N_{test}}} - \rho_{tr}$$

If we define the ratio between the HV intensity of the test area over the ring area as $RHV = \frac{\langle |HV|^2 \rangle_{test}}{\langle |HV|^2 \rangle_{ring}}$ the expression can be modified as:

$$\Lambda = \frac{1 + c}{\rho_{test}^{-1} + \frac{c}{RHV \rho_{ring}}} - \rho_{tr}$$

Additionally we can define the ratio between the polarization ratio in the test over the ring area as $\rho_{test} = \rho_{ring} R \rho$. The expression becomes:

$$\begin{aligned} \Lambda &= \frac{1 + c}{\rho_{ring}^{-1} R \rho^{-1} + c \rho_{ring}^{-1} R H V^{-1}} - \rho_{tr} \\ &= \rho_{ring} \frac{1 + c}{R \rho^{-1} + c R H V^{-1}} - \rho_{tr}, \end{aligned} \quad (9)$$

which is the final expression.
